# Introduction and Theory

Evolutionary paleoecology is the study of the effects of ecological traits and factors on differential rate dynamics, particularly rates of faunal turnover and diversification [61]. Ecological traits are expressed by a taxon, at any level, and are involved in biotic–biotic or biotic–abiotic interactions while ecological factors are the environmental conditions in which a taxon exists (the set of all biotic and abiotic interactors). Diversification is the difference between origination and extinction and is the net pattern of macroevolution. The study of evolutionary paleoecology is therefore the link between environmental (biotic–biotic and biotic–abiotic) interactions and macroevolution. As a corollary to Kitchell [61]’s definition, Allmon [3] states that in order to correctly link ecological interactions to macroevolution, one must focus on the specific traits and factors that may affect the speciation process. Tacitly included in this is the study of how ecological traits are related to extinction [60].

Geographic range size is considered one of the most obvious emergent species level traits [46] because no one property of an organism can explain this trait, is not expressed by a single organisms, and is the combination of multiple traits. Species with larger geographic ranges tend to have lower extinction rates than species with smaller geographic ranges [40, 45, 50, 75, 95]. The effects of traits expressed at the organismal level, such as those relating to environmental preference, together or in concert remain less well understood. Ecological traits have been shown to be related to differential extinction [11, 34, 65, 75], especially the relationship between adaptation to variable environments and increased species longevity. While some research has focused on the indirect effect of organismal traits on longevity [39], the additive or interactive effects of organismal traits alone and their relationship to survival remain understudied. Here I propose to study the how organismal traits are related to extinction and whether emergent traits are necessary for best explaining extinction.

Survival can be considered the fundamental measure evolutionary success because ultimately, a successful lineage is not one that speciated greatly but one that never went extinct [25, 77]. During periods of background extinction it is expected that extinction is non-random with respect to biology [45], so it should be possible to estimate how various ecological traits are correlated with survival [60, 61]. Periods of background extinction also represent the majority of geologic time, remain relatively predictable and change slowly, thus providing a better opportunity to study how traits are related to survival than periods of mass extinction [45, 89]. Additionally, the Law of Constant extinction [110] states that extinction rate within an adaptive zone is taxon-age independent. By analyzing the survival patterns within different adaptive zones during periods of background extinction, it should be possible to determine if extinction is best modeled as age independent or dependent.

It is under this framework that I propose to study how ecological traits associated with environmental preference and range size have affected differential survival and cosmopolitan–endemism dynamics. I will be studying two distantly related and biotically different groups: Permian brachiopods and Cenozoic mammals. Both of these groups are considered to have

very good fossil records able to reflect massive long term evolutionary patterns [71]. These two time periods were chosen because they represent periods of approximately the same length (47 My and 65 My) and of climatic change, global warming and global cooling respectively. Also, these two groups are a marine and terrestrial system respectively and the traits associated with environmental preference and range size (described below) are fundamentally very different.

Importantly, this comparison allows for a series of questions to be asked with regards to emergent properties and the Law of Constant extinction. Brachiopod and mammal survival can be analyzed at the generic level for different adaptive zones (combinations of traits). The age independence or dependence of extinction for these two groups can then be tested. However because there is a known potential bias towards age-dependent extinction when analyzing generic level survival curves [87, 88, 101], the mammalian survival will be further analyzed at the specific level and the differences between the two survival functions will be examined, specifically in whether different traits best model the two curves and if either is age-independent or not. Additionally, the importance of global climatic change in modeling both brachiopod and mammalian survival will be analyzed. In the case of mammalian survival, if global climatic change is found to not be important this does not mean that regional or local climatic changes are not important to survival. By analyzing mammalian community connectedness, it should be possible to estimate how disjoint communities are and if it is reasonable to expect global, regional, or local processes to have dominated and how this may have changed over time.

## Brachiopods, environmental preference, and extinction

*Questions:* In Australasian Permian brachiopods, are traits related to environmental preference correlated with differential survival? Are certain traits more explanatory of survival than others? Does changing climate, habitat or substrate availability affect survival?

*Background and Predictions:* Brachiopods are suspension feeders that are not actively motile, thus the environment conditions of where they occur are extremely important for estimating success. Brachiopod occurrence has been found to be strongly linked to the substrate on which they occur [90, 91]. In contrast, there are no distinct hypotheses related to brachiopod environmental preference and dispersal ability or environmental energetics, both of which are related to substrate occurrence. Because brachiopods are suspension feeders, environmental energetics are important for prey capture and individual survival. The availability of optimal environments becomes a limiting factor on the possible geographic extent of a taxon and the expected extinction rate accompanying geographic range size. In brachiopods, three important traits involved in determining environmental preference are affixing strategy, substrate preference, and habitat preference. While larval mode is considered important in determining range size in marine invertebrates [48, 49], this does not preserve in brachiopods and thus cannot be used for modeling survival [49].

Substrate preference is related to the chemical and physical processes affecting an environment and may limit the range of possible environments in which an organism can optimally survive, thus limiting the possible geographic extent of a taxon. Substrate selection is mitigated via larval chemosensory abilities and thus may act as a weak proxy for larval dispersal ability [48, 49]. Affixing strategy and habitat preference are also related to range size by limiting the possible geographic extent of a taxon. Affixing strategy is the manner by which an individual interfaces with the substrate and different strategies are optimal for different environmental conditions such as flow speed or mud depth [2, 63, 64]. Habitat preference is a statement of the suitability of an environment and the accompanying energy level and availability might act to limit the possible geographic extent of a taxon. Additionally, habitat might capture other factors relating to the environment not captured in substrate preference. While other environmental factors such as temperature, water depth, and environmental energy have not been found to limit the distribution of modern brachiopods [90, 91] though it is unknown if these traits affect survival.

The three principle divisions of substrate affinity are carbonate, clastic, or mixed. These are descriptions of the lithology of the sites at which a taxon is found [7, 33, 58, 74, 75]. The Phanerozoic is characterized by an overall decline in carbonates relative to clastics [33, 74]. Because of this, it is expected that taxa with clastic or mixed affinities will have greater survival than taxa associated with carbonate substrates. If substrate affinity is not found to be important for modeling survival, this may mean that depositional environment has little to no effect on survival and that other factors relating to the environment, measured or unmeasured, are dominant. Additionally, this may mean that depositional environments were not a limiting factor to survival even though it is strongly related to geographic distribution.

The three ways of categorizing affixing strategy are pedunculate, reclining, and cementing. During the Permian, pedunculate taxa are associated with shallow on-shore environments while reclining taxa are associated with deep off-shore environments [20]. These associations are weak as most assemblages are composed of a heterogeneous mix of taxa [20]. Previous global level analysis of brachiopod durations showed that affixing strategy is correlated with longevity [2] and that among endemic taxa, reclining taxa had longer durations than other affixing strategies. Among cosmopolitan taxa, however, pedunculate and cementing taxa had longer durations than all other taxa, both cosmopolitan and endemic. This global analysis mixed taxa from many different geological periods and geographic regions which may produce unfair and biased comparisons. By restricting analysis to a single continuous region, I hope to alleviate these concerns and instead focus on survival of an evolving taxonomic assemblage in a continuous environmental context. If affixing strategy is not important for modeling survival this would mean that, even though affixing strategy is correlated with differential survival [2], it may only be a minor factor. For example, this may indicate that the environmental energetics of Australasia was rather uniform.

The primary ways of classifying habitat preference are on-shore, off-shore, or mixed. Habitat has been frequently invoked for explaining patterns of global diversity [15, 47, 51, 58, 97]. Importantly, habitat preference is related to sea-level and the availability of on-shore habitats

in particular might change dramatically and rapidly over time [76]. On-shore environments have declined in areal extent over the Pharenozoic [79], so it is expected that taxa associated with on-shore habitats would have lower durations than taxa associated with off-shore or mixed habitat preferences. If environmental preference is found to be unimportant when modeling survival, this may mean that sea-level dynamics are rather constant through out Australasia or that other factors may have dominated. The former should be apparent from the rock record itself, an observation that would help determine which processes and conditions were most likely affecting survival.

An important consideration is that taxonomic survival might not be linked to single environments *per se*, but the variability of environments [34, 41, 65]. Adaptation to environmental variability has been found to relate strongly with survival past origination [34]. It is then expected that taxa with mixed substrate affinities and habitat preferences would have longer durations than taxa with single preferences because this means that a taxon’s potential geographic extent is not expressly limited by either of these two traits thus decreasing the expected extinction rate because of an expectedly large range size [40, 45, 50, 75, 95].

During the Permian there was a shift from an “ice house” to a “hot house” world [13, 29, 57, 80]. Australasian taxa are of particular interest because of their proximity to the south pole during the Permian and the repeated glacial activity in the region [13, 29, 57]. According to Olszewski and Erwin [76], however, sea-level and climate change do not wholly explain the brachiopod ecological dynamics experienced in the Permian of Texas. It is then predicted that climate will not be the best sole predictor of brachiopod survival, and that some combination of one or more the above organismal traits will be necessary to best model survival.

*Proposed research:* I propose a survival analysis approach to compare the patterns of survivorship in Permian brachiopods. Survival analysis is the analysis of time-till-event data. In a paleontological context this is the time from origination (first appearance date; FAD) till extinction (last appearance date; LAD). I restrict this analysis to Australasia because it represents a relatively continually sampled and well worked area that preserves the majority of the entire Permian [8, 22, 23, 114]. Multiple models of survival with various combinations, both additive and interactive, of the traits described above will be compared. Substrate preference, affixing strategy, and habitat preference will be assumed to be constant for the duration of the taxon and modeled as time-independent covariates. If and how these traits may have evolved will remain for future study. Climate change will be modeled as either an ancillary Heaviside function or an ancillary time-dependent covariate.

Because substrate and habitat occurrences are not constant at the species level, it is necessary to determine the most probable assignments. The lithology of all occurrences will be classified into one of the three substrate affinity categories following Foote [33] while paleoenvironmental setting of all occurrences will be classified into one of the habitat preferences following Kiessling et al. [59]. Both of these traits will be assigned to all taxa following the Bayesian approach of Simpson and Harnik [102] where assignments are determined as the posterior probability of a taxon’s occurrences in comparison to available options during the duration of said taxon.

Assignment probability,  $P(H_1|E)$ , will be calculated as

$$P(H_1|E) = \frac{P(E|H_1)P(H_1)}{P(E|H_1)P(H_1) + P(E|H_2)P(H_2)} \quad (1)$$

where  $P(H_1)$  and  $P(H_2)$  are the prior probabilities of assignment while  $P(E|H_1)$  and  $P(E|H_2)$  are conditional, binomial probabilities.

In order to assess if the best model of survival is age independent or dependent, the distribution of survival will be modeled using various probability distributions (i.e. exponential, Weibull, log-normal, etc.). An exponential distribution represents the Law of Constant extinction as the rate parameter ( $\lambda$ ) is constant with respect to time. In contrast, the Weibull distribution has two parameters, scale ( $\lambda$ ) and shape ( $k$ ). The scale parameter analogous to the  $\lambda$  of the exponential distribution while the shape parameter describes whether  $\lambda$  is accelerating ( $k < 1$ ), decelerating ( $k > 1$ ), or constant ( $k = 1$ ) with respect to taxon age.

Permian brachiopod occurrence information is available via the Paleobiology Database (PBDB; <http://fossilworks.org>) and is primarily based on the work of Clapham [20–24] and Waterhouse [114].

*Preliminary results* Preliminary analysis of brachiopod survivorship was restricted to genera that originated within the Permian. Survival was analyzed for taxa classified for substrate affinity and habitat preference. For substrate affinity, the priors of Eq. 1 were  $P(H_1) = P(H_2) = 0.5$  and if  $P(H_1|E) > \frac{2}{3}$  then the taxon was considered of carbonate affinity while if  $P(H_1|E) < \frac{1}{3}$  then the taxon was considered to have a clastic affinity. Otherwise, the taxon was considered to have mixed affinity. In the case of habitat affinity, the posterior probability for each habitat (inshore, offshore, none) was calculated using Eq. 1 with priors of  $P(H_1) = \frac{1}{3}$  and  $P(H_2) = \frac{2}{3}$  and the preference with maximum of the three posterior probabilities was the assignment.

Preliminary model fitting with both exponential and Weibull distributions and either or both traits indicated that the best model, based on comparison of AICc scores [1, 19, 44], was the model with substrate affinity as the sole predictor and a Weibull distribution of survival. This model is illustrated below (Fig. 1a). While this is the preliminarily best model of survival, the model with both substrate affinity and habitat preference as additive effects and a Weibull survival distribution may also be considered a good model of survival ( $\Delta AICc \approx 2.9$ ). Additionally, as illustrated by the difference between the nonparametric Kaplan–Meier survival curves and the predictions of the parametric model of survival (Fig. 1a) and there is room for improvement in model specification.

The shape parameter ( $k$ ) of the AICc best model (Fig. 1a) is estimated to be approximately 1.9. As described above, values of  $k$  greater than 1 indicate that failure (extinction) rate is accelerating with respect to taxon age, which may mean that the Law of Constant Extinction does not hold when modeling generic level extinction in brachiopods.

For brachiopod survival based on substrate affinity (Fig. 1a), survival was greater for both carbonate and clastic affinities and lowest for taxa with mixed affinity. Visual inspection

Figure 1: Survivorship curves of Australasian Permian brachiopod genera based on substrate affinity (a) and habitat preference (b). The stepwise functions are nonparametric Kaplan–Meier survival curves for each of the three substrate affinities. The three smooth lines are the predicted survivorship probabilities for taxon of the given age from parametric survival models.

of the estimated survival functions compared to the nonparametric Kaplan–Meier curves indicates that they were adequate fits to the data.

Brachiopod survival with the sole predictor being environmental and a Weibull distribution of survival was not a good model of survival, with an approximate  $\Delta\text{AICc}$  of 33 between this model and the AICc best model. There is a great degree of deviance between the nonparametric Kaplan–Meier curves and model predictions (Fig. 1b). Additionally, this model is not significantly different from the model with only an intercept ( $\chi^2 = 2.41$ ,  $df = 2$ ,  $p = 0.3$ ). This means, preliminarily, that habitat preference alone makes no difference in generic level survival.

Further refinements to these models include modeling survival using other distributions of survival such as a log-normal distribution. Additionally the inclusion of affixing strategy and climate as predictors will increase the understanding of the biology underlying brachiopod generic survival. Additionally, the effects of sampling and uncertain durations will be explored in simulations described below in the context of generic versus specific survival.

## Ecology and survival in Cenozoic mammals

*Questions:* How do ecological traits related to range size affect mammalian taxon duration? Is any single trait the best predictor of mammalian survivorship, or do multiple traits together best model taxon duration? Is climate an important factor in modeling mammalian taxon

duration?

*Background and Predictions:* Three potential constituent traits of range size in mammals are dietary category, locomotor category, and body size [26, 27, 55, 67, 68, 105, 106]. These traits describe different aspects of how an organism interacts with the environment based on either prey availability, dispersal ability, or energetic cost. Dietary categories are defined here as broad trophic categories that subsume further, more specific, classifications. The categories used here are carnivore, herbivore, omnivore, and insectivore. It should be noted that most prior analyses have not included insectivore as a category [55, 81]. Similarly, locomotor categories are defined as combinations of more specific classifications and are broken into arboreal, ground dwelling, and scansorial. Both of these traits are constant at the specific level.

Dietary categories limit abundance because of the availability of resources in a location [18, 26, 53, 100, 112]. Abundance is correlated with occupancy, or the number of localities at which a taxon is found [17, 35, 54]. It follows then that the limits on abundance imposed by resource availability would affect the possible range size of a taxon. Because dietary categories are fundamentally linked to primary productivity and trophic hierarchy, it is expected that the most stable categories would have the greatest survival and the least stable would have the lowest survival. Stability is used here to mean number of “steps” from primary productivity and the related relative requirement of other biotic interactors. As such, herbivores are expected to have greatest survival and carnivores the lowest survival. Omnivorous taxa are expected to have average taxon durations compared to the other two categories. Mammalian herbivores and carnivores have been found to have a greater diversification rate than omnivores [81] which may indicate that these traits are better for survival. However diversification can be caused either by an increase in origination relative to extinction or a decrease in extinction relative to origination. If the latter scenario occurred, this would agree with the predictions from Price et al. [81] that herbivorous and carnivorous taxa would be more successful and have had greater average survival than omnivores. Which scenario occurred, however, is (currently) impossible to determine from a phylogeny of only extant organisms [82] which means that analysis of the fossil record is necessary to estimate which scenario was most likely. If dietary category is not found to be important for modeling survival it may mean that trophic category is not a major factor for determining species level survival and that other factors, such as body size, may dominate.

Locomotor category describes the motility of a taxon and the plausibility of occurrence. For example, an obligate arboreal taxon can only occur in locations with a minimum of tree cover and can most likely only disperse to other environments with suitable tree cover. Dispersal ability is considered important in determining the extent of a taxon’s geographic range [12, 36, 48] and thus any trait that limits dispersal ability would most likely also limit the range size of that organism and increase extinction risk. During the Cenozoic, between the Paleogene–Neogene, there was a shift from a predominately closed environment to a predominately open environment [14, 52, 92]. It is expected then that arboreal taxa during the Paleogene will have a greater expected duration than Neogene taxa, and the opposite

will be true for ground dwelling taxa. In comparison, taxon duration of scansorial taxa is expected to remain relatively similar between the two time periods because it represents a mixed environmental preference that may be viable in either closed or open environments. If locomotor category is not included in the best model of survival this may mean that it is either a poor descriptor of potential dispersal ability or range size or that other factors, both measured or unmeasured, may be of greater importance. The difficulty of a Paleogene–Neogene comparison, which is potentially undermined by heterogeneous preservation potential, will be explored in simulation as described below.

Similar to dietary category, body size has an associated energetic cost in order to maintain homeostasis, which in turn necessitates a sufficient supply of prey items. Because of this, it is expected that larger organisms have higher energetic costs and thus a greater range size in order to obtain necessary resources [18, 26, 26, 68]. It is then expected that, because taxa with larger range sizes have been found to have lower extinction rates, that species with higher average body sizes will have a lower extinction rate than taxa with smaller body sizes. This expectation, however, may not be right. As body size increases, reproductive rate decreases [56], populations are smaller [116], generations are longer [73] all of which can increase extinction risk, as has been observed [28, 66]. However, the relationship between body size and extinction rate at the generic level has been found to vary between continents [66, 109]. By expanding to include a third continent, South America, and analyzing specific level data I hope to elucidate how differences in taxonomic diversity at a continental level might affect body size mediated extinction rate. If body size is found to be unimportant for modeling survival, as in the generic level analysis of Tomiya [109], this means that other biotic or abiotic factors may dominate. This may also mean that individual level home range size does not scale into increased species level range size, and there is therefore no correlated decrease in extinction rate.

The interaction of body size, locomotor category, and dietary category is also extremely important. For example, a small bodied arboreal taxon of any trophic category during the heavily forested and warm time of the Paleogene would be expected at once to have both a small body size determined range, a large potential geographic range determined by locomotion, as well as an increased availability of resources. Together this would mean that relative survival would be expected to be less than, greater than, and greater than average respectively. Determining which factors dominate during the Paleogene, as well as other parts of the Cenozoic, must be done empirically.

*Proposed research:* To analyze differential mammalian survival, I propose a survival analysis approach similar to that described above for Permian brachiopods. Because dietary category and locomotor category are constant at the species level, they will be modeled as time-independent covariates of survival. While a taxon’s average body size may evolve over time, the resolution of the mammal fossil record does not permit observation of this for all Cenozoic taxa. Instead, following previous work, body size will be considered constant with respect to time and will also be modeled as time-independent covariate. The climate proxy  $\delta O^{18}$  oxygen curve [118] will be modeled as an ancillary time-dependent covariate. Also, as described

above for Permian brachiopods, constant versus age dependent extinction rate will be tested  
by comparing the fit of survival to various probability distributions. Additionally, the effect  
of stratification based on the Paleogene–Neogene divide will be assessed in order to determine  
if the time periods had distinct patterns of survival. For this Paleogene–Neogene comparison,  
the principle interest will be with differences in relative trait-based survival between time  
periods and not with exact estimates.

While many analyses of survivorship, such as the one described above for Permian brachiopods,  
are done using generic data [40, 66, 109], there are potential biases in accurately modeling  
specific level processes using generic level data [86, 88, 96, 101, 111]. In order to assess some of  
the differences between generic and specific level survival, I will estimate specific and generic  
level survival models. Using an approach similar to previous work on estimating specific level  
origination and extinction rates from generic level survival curves [32], I will measure the  
deviance between extinction rate directly estimated from the specific survivorship and the  
specific level extinction rates estimated from the generic level survival data. In addition to  
empirical comparison between generic and specific level survival, simulations of diversification  
with varying levels of cryptic speciation (anagenesis). This may also act as a proxy for generic  
level diversification because a lineage having a long duration because it is not correctly broken  
up can be considered analogous to a genus persisting because it continues to speciate.

Homogeneous preservation across taxa is expected to have a minimal and uniform effect  
on estimates of duration and survival [96]. However, the above comparison between the  
Paleogene–Neogene may be biased due to heterogeneous preservation between environments.  
Differential preservation between open and closed environments might strongly bias taxon  
duration estimation and strongly bias comparisons of survival. I propose a series of simulations  
in order to explore the effects of heterogeneous preservation on survival: two groups with  
identical diversification and identical preservation, two groups with identical diversification  
but different preservation, two groups with different diversification but identical preservation,  
and two groups with different diversification and different preservation. Because phylogenies  
are frequently simulated as a time-homogeneous birth-death process, this will be the model  
used to simulate diversification. The expected survival distribution for a time-homogeneous  
birth-death process is exponential because of the age independent rate parameter ( $\lambda$ ).

Mammalian occurrence data will be collected primarily through a combination of the PBDB,  
Neogene Old World Database (NOW; <http://www.helsinki.fi/science/now/>), and mu-  
seum collections. North American fossil mammal data are well represented and vetted in  
the PBDB because of the extensive work of Alroy [4–6]. European fossil mammal data is  
also well represented between the PBDB and NOW. South American fossil mammal data is  
available through the PBDB, but is not particularly well vetted and has poor overall coverage.  
Because of this, South American fossil mammal data will be gathered via various museums  
such as the Field Museum of Natural History and the American Museum of Natural History  
as well as published occurrence compilations. With the South American taxa, taxonomy  
and sampling may not be as well resolved as for North and South America and it may be  
necessary to restrict analysis to the most taxonomically resolved and sampled groups such as

## Community connectedness in Cenozoic mammals

340 *Questions:* How does community composition change over time in terms of the ratio between  
endemic and cosmopolitan taxa? Is there a single global pattern, or do different continents  
342 have different patterns? Do patterns differ between ecological categories? Is global climate  
change an important predictor of these patterns?

344 *Background and Predictions:* Community connectedness is the degree to which localities are  
composed of endemic versus cosmopolitan taxa, and how similar this ratio is across localities.  
346 How community composition changes over time and in relation to organismal traits and  
a changing environment is extremely important for understanding how trophic structure  
348 changes or is maintained over time. Additionally, community connectedness is important for  
understanding the degree to which global, regional, or local scale processes are important for  
350 shaping environmental interactions, both biotic–biotic and biotic–abiotic.

Community connectedness is measured here using four summary statistics: average relative  
352 number of endemic taxa per locality ( $E$ ), average relative locality occupancy per taxon ( $Occ$ ),  
biogeographic connectedness ( $BC$ ), and code length [99]. These summary statistics describe  
354 how unique each locality is on average compared to all others during a time period, how  
relatively widespread taxa are on average during a time period, how evenly distributed taxa  
356 are amongst localities during a time period, and the degree of biogeographic provincially  
during a time period. Analysis of summary statistics both within and between different  
358 regions across the globe allows for the expected relative importance of global versus regional  
versus local processes and how this might change over time to be estimated. If global climate  
360 process are important to patterns of community connectedness and environmental interactions  
than it is expected that these measures will be correlated with global temperature through  
362 time. Additionally, if two or more regions have similar or correlated patterns of community  
connectedness, it is expected that global scale processes may play a roll in shaping the  
364 environment. Regional processes are expected to be important when  $E$  is low,  $Occ$  is high,  
 $BC$  is high, and code length is high. In contrast, local processes are expected to be important  
366 when  $E$  is high,  $Occ$  is low,  $BC$  is low and code length is low. The different process scales  
are not mutually exclusive, however, and one or more scales might be involved in shaping  
368 environmental interactions. Importantly, which process scales are important may change over  
time.

370 In addition to total community connectedness, the dynamics of taxa within various ecological  
categories are important for understanding whether different adaptive zones may be differently  
372 affected by global, regional, or local scale processes. As described above, two important traits  
for potentially determining range size in mammals which are constant at the specific level  
374 are dietary category and locomotor category.

During the Cenozoic there was a global shift from closed, forested habitat to open, savanna-like habitat. Importantly, the timing of this environmental shift was different between continents [107, 108], so patterns of community connectedness may not be globally uniform and could reflect regional differences. The global prediction is that there would have been a relative increase in  $E$  and code length accompanied by a decrease in  $BC$  and  $Occ$  in arboreal taxa over time. The opposite is expected for terrestrial taxa. These expectations are because forested environments would likely have become increasingly patchily distributed, particularly during the Neogene compared to the Paleogene.

Based on prior work, it is expected that the patterns of biogeographic community connectedness for herbivorous taxa in a region would be most similar to that for all regional taxa and potentially “drive” the regional pattern, partially because on average this category represents the majority or plurality of taxa [54]. In contrast, community connectedness for carnivorous taxa is expected to remain constant over time or be correlated with herbivore patterns. Finally, omnivorous taxa are not expected to be correlated with the patterns of either herbivorous or carnivorous taxa and have either relatively constant or random patterns of community connectedness over time. These predictions are based on the differences in resilience and relationship to primary productivity, with herbivores being more resilient than carnivores and omnivores being random in their resilience [55]. Resilience is defined here as the ability for a taxon to increase in commonness (occupancy) after a decline [55].

An additional global trend during the Cenozoic was the shift from a “hot house” environment to an “ice house” environment [117, 118]. This transition was accompanied by major shifts in global climatic envelopes and the reorganization of mammalian communities [6, 14, 30, 35, 52]. For mammalian community connectedness there are two possible scenarios. First, while the environment was shifting, lineages may have adapted in place and overall trophic structure and community connectedness would have remained relatively constant through time, as observed during the Neogene of Europe [55]. Alternatively, species may have shifted ranges and changed the average set of taxa present at a locality which would be associated with non-stationary trophic structure and community connectedness.

At a regional scale, North American community connectedness is expected to follow the global predictions described above because the vast amount of prior synthesis has focused on North America [4–6, 9, 10, 14, 30, 37, 38, 103, 104]. However, the effect of global climate change on North American diversity remains unresolved and controversial [6, 10, 14, 30], thus it is necessary to determine empirically when global versus regional versus local scale processes may have dominated and how that may have changed over time.

The European mammalian fossil record is also well studied, though research has primarily focused on the Neogene [54, 55, 66, 83–85]. An important aspect about the European record is that during the Neogene there was little shift in relative dietary category abundance [55] and that the patterns within herbivores (browse–graze transition) were mostly driven by abundant, cosmopolitan taxa [54]. It is predicted then that herbivores will demonstrate the same patterns of community connectedness as Europe as a whole, while omnivores and

carnivores will be different from that of herbivores and may demonstrate random or constant patterns of community connectedness through time.

Patterns of community connectedness for South American mammalian fauna are comparatively less synthesized than those of North American and Europe. Instead, cross-continental dynamics between North and South America during the Neogene are much more studied [72]. The South American mammalian faunal record reflects two distinct biotic provinces between the North and the South [31, 69, 70, 78]. Because of this, it is expected that South America will have a different pattern of community connectedness than either North America or Europe. Also, there is an expected dramatic increase occupancy in land-dwelling herbivores relative to arboreal and scansorial taxa related to the aridification of high-latitude South America. Additionally, because of this strong biome distinction, it is predicted that provinciality will be high but remain constant over time.

*Proposed research:* Using an approach proposed by Sidor et al. [99] and Vilhena et al. [113], I will use bipartite biogeographic networks in order to understand patterns of community connectedness. Networks are between taxa, here defined as species, and localities, defined as 2x2 grid cells from an equal-area map projection. Networks will be made for every 2 million year bin of the Cenozoic. This bin width is chosen to always have a minimum of two localities present. Networks will also be constructed for taxa separated by dietary and locomotor category. Previous studies of mammalian occurrence patterns have restricted analysis to large bodied and well studied groups, such as Primates and Artiodactyls, in order to account for potential sampling and taxonomic biases. Here, analysis will be done using all available taxa and with a restricted sample of just major groups in order to observe any differences in patterns of community connectedness.

Community connectedness will be measured using the four summary statistics described above.  $E$  is defined as  $E = \frac{\sum_{i=1}^L \frac{u_i}{n_i}}{L}$  where  $L$  is as the number of localities,  $u$  is the number of taxa unique to a locality, and  $n$  is the number of taxa present at a locality. This is a measure of how unique localities are on average.  $Occ$  is the number of localities a taxon is, on average, found at and is defined  $Occ = \frac{\sum_{i=1}^N \frac{l_i}{L}}{N}$  where  $N$  is as the number of taxa present in the biogeographic network and  $l$  is the number of localities a taxon occurred in.  $BC$  is a measurement of the shared taxa between localities and is defined  $BC = \frac{O-N}{LN-N}$  where  $O$  is the total number of taxonomic occurrences.  $BC$  ranges from 0 to 1, with 0 meaning that each locality completely disconnected from all other localities and 1 indicating that all taxa are presents at all localities.

Code length is a measure of the information flow [98] of a graph as estimated from the behavior of a random surfer [16] on a graph and how often it visits each node and it's behavior with regards to moving into and out of different regions of the graph. Code length is the minimum length of a binary code for describing the behavior the surfer and the community structure of the nodes and is estimated via the map equation [93, 94]. The logic of the map equation is that a good map compresses reality into as few symbols as possible thus we want to compress as many nodes as possible into as few symbols as possible. Our goal is to

represent a graph better than just assigning a unique Huffman code to each node [43, 93]. By compressing multiple nodes into a single code block, we decrease the minimum coding length of a network and a network with a low code length has more nodes compressed into distinct subunits/provinces without losing the underlying information flow of the graph. In the case of measuring community connectedness, a low code length means greater site distinctness and provinciality than a graph with a high code length [99].

Phylogenetic similarity between localities may play an important role in community structuring [115] such as closely related taxa being “repulsed” due to competitive exclusion or “clumped” because of environmental filtering. As a preliminary approach, for every pairwise combination of localities during a time period an informal phylogeny will be constructed for the pool of all taxa present in both localities. This informal phylogeny will be based solely on available taxonomic information such as order, family, and genus assignments with each of these levels being a completely unresolved polytomy. While there is formal phylogenetic information for many mammals that would provide greater resolution, this should not be necessary in most cases because only the general “phylogenetic proximity” is necessary for this study. Using an (informal) phylogeny, a number of measures of phylogenetic similarity can be measured for example the relative mean pairwise distance between all taxa at a locality [115] or the related phylogenetic species variability of a single locality Helmus et al. [42]. These values, calculated for all localities, can then be averaged to give an estimate of average phylogenetic similarity over the Cenozoic which can be used as a partial correlate or covariate for modeling changes in community connectedness.

The next step is to compare patterns of community connectedness both within and between regions in order to understand if global, regional, or local scale processes dominate. Additionally, comparisons will be done between the different dietary and locomotor categories both within and between regions to determine which scale processes may be affecting either trait. The approach and methodology to accomplish these analyses is currently under development. Additionally, the possibility of integrating locality–locality distance or some other measure of topology will be explored, especially how this relates to code length and provinciality in general.

The data necessary to complete this study is the same as for the above analysis of mammalian survival.

*Preliminary results* Preliminary results of the community connectedness patterns of both North America and Europe based on PBDB data are presented here (Fig. 2). Both regions have qualitatively different patterns of community connectedness, primarily during the Paleogene. Almost all four of the summary statistics are extremely volatile over the Cenozoic, especially for Europe. However, some interesting qualitative patterns are present.

There is a qualitative decrease in *Occ* in Europe until approximately the start of the Neogene (approximately 23 My), indicating that the average taxon is becoming generally less cosmopolitan over time. In contrast, North American *Occ* is qualitatively stationary over the entire Cenozoic and almost always lower than that observed for Europe. This means that, on

Figure 2: Biogeographic network summary statistics for mammalian communities in North America (dashed line) and Europe (solid line). The summary statistics are, clockwise from top left: biogeographic connectedness (BC), code length, average relative locality occupancy per taxon (Occ), and average relative number of endemic taxa per locality (E). Blue lines are generalized additive model smooths and are presented to illustrate the overall pattern for each region.

average, North American taxa are present in very few localities at any given point in time.

In Europe there is a qualitative rise in *BC* in the first few million years of the Cenozoic, but afterwards remains relatively stationary meaning that the average proportion of shared taxa remained qualitatively stationary. In comparison, North American *BC* remains stationary with a greater amount of shared taxa than Europe for the first half of the Cenozoic followed by a decrease and another plateau at the end of the Cenozoic.

In Europe, there is a over all qualitative decrease in *E* while in North America there is a qualitatively constant *E* over the Cenozoic with a slight decrease in the Neogene. As discussed above, *E* is a measure of relative uniqueness of a locality on average. Qualitatively, North America retained approximately the same amount of site uniqueness through out the Cenozoic. While the pattern of the European record shows a qualitatively nonmonotonic decrease in locality uniqueness.

The code length of European biogeographic networks increases qualitatively over the entire Cenozoic, while code length of North American networks remains relatively constant until the Neogene when there is a qualitative increase. Initial interpretation of these results indicates that North America maintains a relatively stationary degree of provinciality while Europe

has a qualitatively decreasing degree of provinciality.

## Synthesis of proposed research

Underlying all of the above is a foundational question in paleobiology: why do certain taxa go extinct while others do not? In the context of evolutionary paleoecology, this question can be rephrased as “how do the set of all biotic–biotic and biotic–abiotic interactions a taxon experiences over time (i.e. adaptive zone 103) affect extinction risk?” Related to this is the Law of Constant Extinction which states that extinction risk for a given adaptive zone is taxon–age independent [110]. It is asserted that the Law of Constant Extinction only holds during periods of relatively constant environment even though this was not the context for the initial observation [65, 110] which can be interpreted as the set of dominant non-organism mediated processes do not fluctuate or fluctuate in a known manner. By understanding which non-organism mediated processes may be shaping the environment (set of all possible biotic and abiotic interactors) and how they change over time and phrasing analysis of extinction in this context, it may be possible to “test” the Law of Constant Extinction.

The first two studies proposed above investigate how organismal traits potentially related to environmental preference affect extinction rate. In effect, these traits may determine the “bounds” of a taxon’s adaptive zone by limiting the total set of interactions to just those for which the taxon is adapted. The final proposed study aims to estimate what non-organism mediated processes (global, regional, and/or local) may be dominate in shaping the environment and the related set of adaptive zones. Between these studies, as well the use of two desperate groups, it should be possible to determine when, what, and if certain variables matter for survival and potentially how they matter.

# Timeline

534 Spring/Summer 2014

- Evolution Meeting: preliminary brachiopod survival results

536 • South American fossil mammal data from Field Museum of Natural History collections

Fall 2014/Winter 2015

538 • GSA: survivorship simulation for anagenesis and sampling

- Doctoral Dissertation Improvement Grant

540 Spring/Summer 2015

- Evolution Meeting: mammalian survivorship analysis for North America and Europe

542 • South American fossil mammal data from American Museum of Natural History collections

544 • write and submit survivorship simulation paper

Fall 2015/Winter 2016

546 • SVP or GSA: mammalian biogeographic connectedness

- write and submit mammal connectedness paper

548 Spring/Summer 2016

- Evolution Meeting: brachiopod survival analysis results

550 • write and submit brachiopod survival paper

Fall 2016/Winter 2017

552 • SVP or GSA: mammalian survivorship analysis

- write and submit mammal survival paper

554 Spring/Summer 2017

- Evolution Meeting

556 • write and submit review/philosophy paper

- **Defend**
