Introduction and Theory

Evolutionary paleoecology is the study of the effects of ecological traits and factors on differential rate dynamics, particularly rates of faunal turnover and diversification [60]. Ecological traits and factors are traits expressed by a taxon, at any level, that are involved with biotic–biotic or biotic–abiotic interactions. Diversification is the difference between origination and extinction and is the net pattern of macroevolution. The study of evolutionary paleoecology is therefore the link between environmental (biotic–biotic and biotic–abiotic) interactions and macroevolution. As a corollary to Kitchell [60]’s definition, Allmon [3] states that in order to correctly link ecological interactions to macroevolution, one must focus on the specific traits and factors that may affect the speciation process. Tacitly included in this is the study of how ecological traits are related to extinction [59].

Geographic range size is considered one of the best recognized species level traits [46] and is considered emergent because no one property of an organism can explain this trait and it is instead the combination of multiple traits. Species with larger geographic ranges tend to have lower extinction rates than species with smaller geographic ranges [39, 44, 50, 73, 91]. The effects of organismal traits, such as those relating to environmental preference, together or in concert remain less well understood. Ecological traits have been shown to be related to differential extinction [11, 33, 64, 73], especially the relationship between adaptation to variable environments and increased species longevity. While some research has focused on the indirect effect of organismal traits on longevity [38], the additive or interactive effects of organismal traits alone and their relationship to survival remain understudied. Here I propose to study the how organismal traits related to range size are related to extinction and if emergent traits are necessary for best explaining extinction.

Survival can be considered the fundamental measure evolutionary success because ultimately, a successful lineage is not one that speciated greatly but one that never went extinct [25, 75]. During periods of background extinction it is expected that extinction is non-random with respect to biology [44], so it should be possible to estimate how various ecological traits are correlated with survival [59, 60]. Periods of background extinction also represent the majority of geologic time, remain relatively predictable and change slowly, thus providing a better opportunity to study how traits are related to survival than periods of mass extinction [44, 87]. Additionally, the Law of Constant extinction [106] states that extinction rate within an adaptive zone is taxon-age independent. By analyzing the survival patterns within different adaptive zones during periods of background extinction, it should be possible to determine if extinction is best modeled as age independent or dependent (accelerating/decelerating).

It is under this framework that I propose to study how ecological traits associated with environmental preference and range size have affected differential survival and cosmopolitan-endemism dynamics. I will be studying two distantly related and biotically different groups: Permian brachiopods and Cenozoic mammals. Both of these groups are considered to have very good fossil records able to reflect massive long term evolutionary patterns [70]. These two time periods were chosen because they represent periods of approximately the same length (47

My and 65 My) and of climatic change, global warming and global cooling respectively. Also, these two groups are a marine and terrestrial system respectively and the traits associated with environmental preference and range size (described below) are fundamentally very different.

Importantly, this comparison allows for a series of questions to be asked with regards to emergent properties and the Law of Constant extinction. Brachiopod and mammal survival can be analyzed at the generic level for different adaptive zones (combinations of traits). The age independence or dependence of extinction for these two groups can then be tested. However because there is a known potential bias towards age-dependent extinction when analyzing generic level survival curves [85, 86, 97], the mammalian survival will be further analyzed at the specific level and the differences between the two survival functions will be examined, specifically in whether different traits best model the two curves and if either is age-independent or not. Additionally, the importance of global climatic change in modeling both brachiopod and mammalian survival will be analyzed. In the case of mammalian survival, if global climatic change is found to not be important this does not mean that regional or local climatic changes are not important to survival. By analyzing mammalian community connectedness, it should be possible to estimate how disjoint communities are and if it is reasonable expect global, regional, or local processes to have dominated and how this may have changed over time.

Brachiopods, environmental preference, and extinction

Questions: In Australasian Permian brachiopods, are traits related to environmental preference correlated with differential survival? Are certain traits more explanatory of survival than others? Does changing climate, habitat or substrate availability affect survival?

Background and Predictions: In brachiopods, three important traits involved in determining environmental preference are affixing strategy, substrate preference, and habitat preference. While larval mode is considered important in determining range size in marine invertebrates [48, 49], this does not preserve in brachiopods and thus cannot be used for modeling survival [49]. Because brachiopods are obligate filter feeders, environmental energetics is important for prey capture and individual survival. Thus, the availability of optimal environments becomes a limiting factor on the possible geographic extent of a taxon and the expected extinction rate accompanying geographic range size.

Substrate preference is related to the chemical and physical processes affecting an environment and may limit the range of possible environments in which an organism can optimally survive, thus limiting the possible geographic extent of a taxon. Substrate selection is mitigated via larval chemosensory abilities and thus may act as a weak proxy for larval dispersal ability [48, 49]. Affixing strategy and habitat preference are also related to range size by limiting the possible geographic extent of a taxon. Affixing strategy is the manner by which an individual

78 interfaces with the substrate and different strategies are optimal for different environmental
conditions such as flow speed or mud depth [2, 62, 63]. Habitat preference is a statement of
80 the suitability of an environment and the accompanying environmental energy level and acts
as a limit on the possible geographic extent of a taxon.

82 The three principle classifications of substrate affinity are carbonate, clastic, or mixed. These
are descriptions of the lithology of the sites at which a taxon is found [7, 32, 57, 72, 73]. The
84 Phareozoic is characterized by an overall decline in carbonates relative to clastics [32, 72].
Because of this, it is expected that taxa with clastic or mixed affinities will have greater
86 survival than taxa associated with carbonate substrates. If substrate affinity is not found
to be important for modeling survival, this may mean that depositional environment has
88 little to no affect on survival and that other factors relating to the environment, measured
or unmeasured, are dominant. Additionally, this may mean that depositional environments
90 were relatively constant throughout the Permian of Australasia or was at least not a limiting
factor to survival.

92 The three principle ways of classifying affixing strategies are pedunculate, reclining, and
cementing. During the Permian, pedunculate taxa are associated with shallow on-shore
94 environments while reclining taxa are associated with deep off-shore environments [20]. These
associations are weak as most assemblages are composed of a heterogeneous mix of taxa [20].
96 Previous analysis of brachiopod durations showed that affixing strategy is correlated with
longevity [2] and that among endemic taxa, reclining taxa had longer durations than other
98 affixing strategies. Among cosmopolitan taxa, however, pedunculate and cementing taxa had
longer durations than all other taxa. If affixing strategy is not important for modeling survival
100 this would mean that, even though affixing strategy is correlated with differential survival
[2], it may only be a minor factor. For example, this may indicate that the environmental
102 energetics of the Australasia was rather uniform.

The primary ways of classifying habitat preference are on-shore, off-shore, or mixed. Habitat
104 has been frequently invoked for explaining patterns of global diversity [15, 47, 51, 57, 93].
Importantly, habitat preference is related to sea-level and the availability of on-shore habitats
106 in particular might change dramatically and rapidly overtime [74]. On-shore environments
have declined in areal extent over the Phareozoic [77] so it is expected that taxa associated
108 with on-shore habitats would have lower durations than taxa associated with off-shore or
mixed habitat preferences. If environmental preference is found to be unimportant when
110 modeling survival, this may mean that sea-level dynamics are rather constant through out
Australasia or that other factors may have dominated.

112 An important consideration is that taxonomic survival might not be linked to single environ-
ments *per se*, but the variability of environments [33, 40, 64]. Adaptation to environmental
114 variability has been found to relate strongly with survival past origination [33]. It is then
expected that taxa with mixed substrate affinities and habitat preferences would have longer
116 durations than taxa with single preferences because this means that a taxon's potential
geographic extent is not expressly limited by either of these two traits and thus decreasing

the expected extinction rate because of an expectedly large range size [39, 44, 50, 73, 91].

During the Permian there was a shift from an “ice house” to a “hot house” world [13, 28, 56, 78]. Australasian taxa are of particular interest because of their proximity to the south pole during the Permian and the repeated glacial activity in the region [13, 28, 56]. According to Olszewski and Erwin [74], however, sea-level and climate change do not wholly explain the brachiopod ecological dynamics experienced in the Permian of Texas. The prediction then is that the best model of brachiopod survivorship will have to have one of the three traits described above while the necessity of climate as a predictor in the best model of survivorship is necessary to determine empirically.

Proposed research: I propose a survival analysis approach to compare the patterns of survivorship in Permian brachiopods. Survival analysis is the analysis of time-till-event data. In a paleontological context this is the time from origination (first appearance date; FAD) till extinction (last appearance date; LAD). I restrict this analysis to Australasia because it represents a relatively continually sampled and well worked area that preserves the majority of the entire Permian [8, 22, 23, 110]. Multiple models of survival with various combinations, both additive and interactive, of the traits described above will be compared. Substrate preference, affixing strategy, and habitat preference will be assumed to be constant for the duration of the taxon and modeled as time-independent covariates. If and how these traits may have evolved will remain for future study. Climate change will be modeled as either an ancillary Heaviside function or an ancillary time-dependent covariate.

Because substrate and habitat occurrences are not constant at the species level, it is necessary to determine the most probable of assignments. The lithology of all occurrences will be classified into one of the three substrate affinity categories following Foote [32] while paleoenvironmental setting of all occurrences will be classified into one of the habitat preferences following Kiessling et al. [58]. Both of these traits will be assigned to all taxa following the Bayesian approach of Simpson and Harnik [98] where assignments are determined as the posterior probability of a taxon’s occurrences in comparison to available options during the duration of said taxon. Assignment probability, $P(H_1|E)$, will be calculated as

$$P(H_1|E) = \frac{P(E|H_1)P(H_1)}{P(E|H_1)P(H_1) + P(E|H_2)P(H_2)} \quad (1)$$

where $P(H_1)$ and $P(H_2)$ are the prior probabilities of assignment while $P(E|H_1)$ and $P(E|H_2)$ are conditional, binomial probabilities.

In order to assess if the best model of survival is age independent or dependent, the distribution of survival will be modeled using various probability distributions (i.e. exponential, Weibull, log-normal, etc.). An exponential distribution represents the Law of Constant extinction as the rate parameter (λ) is constant with respect to time. In contrast, the Weibull distribution has two parameters, scale (λ) and shape (k). The scale parameter analogous to the λ of the exponential distribution while the shape parameter describes whether λ is accelerating ($k < 1$), decelerating ($k > 1$), or constant ($k = 1$) with respect to taxon age.

Permian brachiopod occurrence information is available via the Paleobiology Database (PBDB; <http://fossilworks.org>) and is primarily based on the work of Clapham [20–24] and Waterhouse [110].

Preliminary results Preliminary analysis of brachiopod survivorship was restricted to genera that originated within the Permian. Survival was analyzed for taxa classified for substrate affinity and habitat preference. For substrate affinity, the priors of Eq. 1 were $P(H_1) = P(H_2) = 0.5$ and if $P(H_1|E) > \frac{2}{3}$ then the taxon was considered of carbonate affinity while if $P(H_1|E) < \frac{1}{3}$ then the taxon was considered to have a clastic affinity. Otherwise, the taxon was considered to have mixed affinity. In the case of habitat affinity, the posterior probability for each habitat (inshore, offshore, none) was calculated using Eq. 1 with priors of $P(H_1) = \frac{1}{3}$ and $P(H_2) = \frac{2}{3}$ and the preference with maximum of the three posterior probabilities was the assignment.

Preliminary model fitting with both exponential and Weibull distributions and either or both traits indicated that the best model, based on comparison of AICc scores [1, 19, 43], was the model with substrate affinity as the sole predictor and a Weibull distribution of survival. This model is illustrated below (Fig. 1a). While this is the preliminarily best model of survival, the model with both substrate affinity and habitat preference as additive effects and a Weibull survival distribution may also be considered a good model of survival ($\Delta\text{AICc} \approx 2.9$). Additionally, as illustrated by the difference between the nonparametric Kaplan–Meier survival curves and the predictions of the parametric model of survival (Fig. 1a) and there is room for improvement in model specification.

The shape parameter (k) of the AICc best model (Fig. 1a) is estimated to be approximately 1.9. As described above, values of k greater than 1 indicate that failure (extinction) rate is accelerating with respect to taxon age, which may mean that the Law of Constant Extinction does not hold when modeling generic level extinction in brachiopods.

For brachiopod survival based on substrate affinity (Fig. 1a), survival was greater for both carbonate and clastic affinities and lowest for taxa with mixed affinity. Visual inspection of the estimated survival functions compared to the nonparametric Kaplan–Meier curves indicates that they were adequate fits to the data.

Brachiopod survival with the sole predictor being environmental and a Weibull distribution of survival was not a good model of survival, with an approximate ΔAICc of 33 between this model and the AICc best model. There is a great degree of deviance between the nonparametric Kaplan–Meier curves and model predictions (Fig. 1b). Additionally, this model is not significantly different from the model with only an intercept ($\chi^2 = 2.41$, $df = 2$, $p = 0.3$). This means, preliminarily, that habitat preference alone makes no difference in generic level survival.

Further refinements to these models include modeling survival using other distributions of survival such as a log-normal distribution. Additionally the inclusion of affixing strategy and climate as predictors will increase the understanding of the biology underlying brachiopod

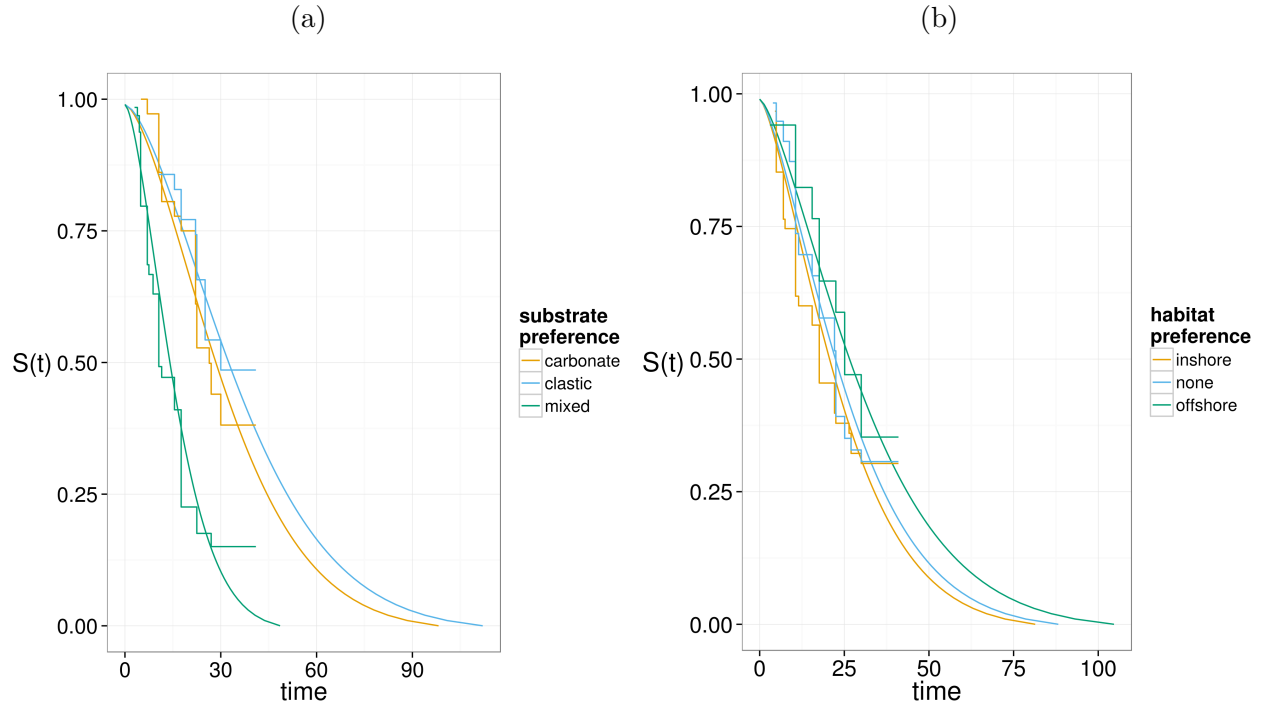

Figure 1: Survivorship curves of Australasian Permian brachiopod genera based on substrate affinity (a) and habitat preference (b). The three stepwise functions are nonparametric Kaplan–Meier survival curves for each of the three substrate affinities. The three smooth lines are the predicted survivorship probabilities for taxon of the given age from the parametric model of generic survivorship.

194 generic survival.

Ecology and survival in Cenozoic mammals

196 *Questions:* How do ecological traits related to range size affect mammalian taxon duration? Is
any single trait the best predictor of mammalian survivorship, or do multiple traits together
198 best model taxon duration? Is climate an important factor in modeling mammalian taxon
duration?

200 *Background and Predictions:* Three potential constituent traits of range size in mammals are
dietary category, locomotor category, and body size [26, 27, 55, 66, 67, 101, 102]. These traits
202 describe different aspects of how an organism interacts with the environment based on either
prey availability, dispersal ability, or energetic cost. Dietary categories are defined here as
204 broad trophic categories that subsume further, more specific, classifications. The categories
used here are carnivore, herbivore, omnivore, and insectivore. It should be noted that most

prior analyses have not included insectivore as a category [55, 79]. Similarly, locomotor categories are defined as combinations of more specific classifications and are broken into arboreal, ground dwelling, and scansorial. Both of these traits are constant at the specific level.

Dietary categories limit abundance because of the availability of resources in a location [18, 26, 53, 96, 108]. Abundance is correlated with occupancy, or the number of localities at which a taxon is found [17, 34, 54]. It follows then that the limits on abundance imposed by resource availability would affect the possible range size of a taxon. Because dietary categories are fundamentally linked to primary productivity and trophic hierarchy, it is expected that the most stable categories would have the greatest survival and the least stable would have the lowest survival. As such, herbivores are expected to have greatest survival and carnivores the lowest survival. Omnivorous taxa are expected to have average taxon durations compared to the other two categories. Mammalian herbivores and carnivores have been found to have a greater diversification rate than omnivores [79] which may indicate that these traits are better for survival. However diversification can be caused either by an increase in origination relative to extinction or a decrease in extinction relative to origination. If the latter scenario occurred, this would agree with the predictions from Price et al. [79] that herbivorous and carnivorous taxa would be more successful and have had greater average survival than omnivores. Which scenario occurred, however, is (currently) impossible to determine from a phylogeny of only extant organisms [80] which means that analysis of the fossil record is necessary to estimate which scenario was most likely. If dietary category is not found to be important for modeling survival it may mean that trophic category is not a major factor for determining species level survival and that other factors, such as body size, may dominate.

Locomotor category describes the motility of a taxon and the plausibility of occurrence. For example, an obligate arboreal taxon can only occur in locations with a minimum of tree cover and can most likely only disperse to other environments with suitable tree cover. Dispersal ability is considered important in determining the extent of a taxon's geographic range [12, 35, 48] and thus any trait that limits dispersal ability would most likely also limit the range size of that organism and increase extinction risk. During the Cenozoic, between the Paleogene–Neogene, there was a shift from a predominately closed environment to a predominately open environment [14, 52, 88]. It is expected then that arboreal taxa during the Paleogene will have a greater expected duration than Neogene taxa, and the opposite will be true for ground dwelling taxa. In comparison, taxon duration of scansorial taxa is expected to remain relatively similar between the two time periods because it represents a mixed environmental preference that may be viable in either closed or open environments. If locomotor category is not included in the best model of survival this may mean that it is either a poor descriptor of potential dispersal ability or range size or that other factors, both measured or unmeasured, may be of greater importance.

Similar to dietary category, body size has an associated energetic cost in order to maintain homeostasis, which in turn necessitates a sufficient supply of prey items. Because of this, it is expected that larger organisms have higher energetic costs and thus a greater range

size in order to obtain necessary resources [18, 26, 26, 67]. It is then expected that, because taxa with larger range sizes have been found to have lower extinction rates, that species with higher average body sizes will have a lower extinction rate than taxa with smaller body sizes. However, the relationship between body size and extinction rate at the generic level has been found to vary between continents [65, 105]. By expanding to include a third continent, South America, and analyzing specific level data I hope to elucidate how differences in taxonomic diversity at a continental level might affect body size mediated extinction rate. If body size is found to be unimportant for modeling survival, as in the generic level analysis of Tomiya [105], this means that other biotic or abiotic factors may dominate. This may also mean that individual level home range size does not scale into increased species level range size, and there is therefore no correlated decrease in extinction rate.

The interaction of body size, locomotor category, and dietary category is also extremely important. For example, a small bodied arboreal taxon of any trophic category during the heavily forested and warm time of the Paleogene would be expected at once to have both a small body size determined range, a large potential geographic range determined by locomotion, as well as an increased availability of resources. Together this would mean that relative survival would be expected to be less than, greater than, and greater than average respectively. Determining which factors dominate during the Paleogene, as well as other parts of the Cenozoic, must be done empirically.

Proposed research: To analyze differential mammalian survival, I propose a survival analysis approach similar to that described above for Permian brachiopods. Because dietary category and locomotor category are constant at the species level, they will be modeled as time-independent covariates of survival. While a taxon's average body size may evolve over time, the resolution of the mammal fossil record does not permit observing of this for all Cenozoic taxa. Instead, following previous work, body size will be considered constant with respect to time and will also be modeled as time-independent covariate. The climate proxy δO^{18} oxygen curve [113] will be modeled as an ancillary time-dependent covariate. Also, as described above for Permian brachiopods, constant versus age dependent extinction rate will be tested by comparing the fit of survival to various probability distributions. Additionally, the effect of stratification based on the Paleogene/Neogene divide will be assessed in order to determine if the time periods had distinct patterns of survival.

While many analyses of survivorship, such as the one described above for Permian brachiopods, are done using generic data [39, 65, 105], there are potential biases in accurately modeling specific level processes using generic level data [84, 86, 92, 97, 107]. Anagenesis, hierarchical selection, and taxa that did not go extinct in the time frame of interest may all bias models of survival [84, 86, 97, 107]. Interestingly, the effect of incomplete sampling on estimation of survivorship curves appears rather minimal and uniform [92]. The problems involving taxa that did not go extinct have mostly been dealt with following advances in modeling right-censored and interval data [61].

In order to assess differences between generic and specific level survival, I will estimate

specific and generic level survival models. Using an approach similar to previous work on
estimating specific level origination and extinction rates from generic level survival curves
[31], I will measure the deviance between extinction rate directly estimated from the specific
survivorship and the specific level extinction rates estimated from the generic level survival
data. Additionally, in order to understand the effects of anagenesis and sampling on survival,
I also propose a simulation study where these two properties are varied and the difference
between the known survival patterns and the estimated survival patterns will be measured.
Because phylogenies are frequently simulated as a time-homogeneous birth-death process,
this will be the model used to simulate the phylogenies underlying the diversification process.
For a time-homogeneous birth-death process, it is expected survival will be distributed
exponentially because of the age independent rate parameter (λ). While sampling has been
found to have minimal and uniform effect on paleontological survival analysis assuming
sampling is homogeneous across taxa [92], the affect of anagenesis is unknown.

Mammalian occurrence data will be collected primarily through a combination of the PBDB,
Neogene Old World Database (NOW; <http://www.helsinki.fi/science/now/>), and mu-
seum collections. North American fossil mammal data is very well represented and vetted in
the PBDB because of the extensive work of Alroy [4–6]. European fossil mammal data is
also well represented between the PBDB and NOW. South American fossil mammal data is
available through the PBDB, but is not particularly well vetted and has poor overall coverage.
Because of this, South American fossil mammal data will be gathered via various museums
such as the Field Museum of Natural History and the American Museum of Natural History
as well as published occurrence compilations. With the South American taxa, taxonomy
and sampling may not be as well resolved as for North and South America and it may be
necessary to restrict analysis to the most taxonomically resolved and sampled groups such as
Notoungulata, Marsupials, Carnivora, and Primates.

Community connectedness in Cenozoic mammals

Questions: How does the relationship between endemic and cosmopolitan taxa in average
community composition change over time? Is there a single global pattern, or do different
continents have different patterns? Do patterns differ between ecological categories? Is global
climate change an important predictor of these patterns?

Background and Predictions: Community connectedness is the degree to which localities are
composed of endemic versus cosmopolitan taxa, and how similar this ratio is across localities.
How community composition changes over time and in relation to organismal traits and
a changing environment is extremely important for understanding how trophic structure
changes or is maintained over time. Additionally, community connectedness is important for
understanding whether global, regional, or local scale processes are important for shaping
environmental interactions, both biotic–biotic and biotic–abiotic.

Community connectedness is measured here using four summary statistics: average relative number of endemic taxa per locality (E), average relative locality occupancy per taxon (Occ), biogeographic connectedness (BC), and code length [95]. These summary statistics describe how unique each locality is on average compared to all others during a time period, how relatively widespread taxa are on average during a time period, how evenly distributed taxa are amongst localities during a time period, and the degree of biogeographic provinciality during a time period. Analysis of summary statistics both within and between different regions across the globe allows for the expected relative importance of global versus regional versus local processes and how this might change over time to be estimated. If global climate process are important to patterns of community connectedness and environmental interactions than it is expected that these measures will be correlated with global temperature through time. Additionally, global scale processes would be expected to be important if two or more regions similar and/or correlated patterns of community connectedness. Regional processes are expected to be important when E is low, Occ is high, BC is high, and code length is high. In contrast, local processes are expected to be important when E is high, Occ is low, BC is low and code length is low. The different process scales are not mutually exclusive, however, and one or more scales might be involved in shaping environmental interactions. Importantly, which process scales are important may change over time.

In addition to total community connectedness, the dynamics of taxa within various ecological categories are important for understanding whether different adaptive zones may be differently affected by global, regional, or local scale processes. As described above, two important traits for potentially determining range size in mammals which are constant at the specific level are dietary category and locomotor category.

During the Cenozoic there was a global shift from closed, forested habitat to open, savanna-like habitat. Importantly, the timing of this environmental shift was different between continents [103, 104], so patterns of community connectedness may not be globally uniform and could reflect regional differences. The global prediction is that there would have been a relative increase in E and code length accompanied by a decrease in BC and Occ in arboreal taxa over time. The opposite is expected for terrestrial taxa. These expectations are because forested environments would likely have become increasingly patchily distributed, particularly during the Neogene compared to the Paleogene.

Based on prior work, it is expected that the patterns of biogeographic community connectedness for herbivorous taxa in a region would be most similar to that for all regional taxa, partially because on average this category represents the majority or plurality of taxa [54]. In contrast, community connectedness for carnivorous taxa is expected to remain constant over time or be correlated with herbivore patterns. Finally, omnivorous taxa are not expected to be correlated with the patterns of either herbivorous or carnivorous taxa and have either relatively constant or random patterns of community connectedness over time. These predictions are based on the differences in resilience and relationship to primary productivity, with herbivores being more resilient than carnivores and omnivores being random in their resilience [55].

An additional global trend during the Cenozoic was the shift from a “hot house” environment to an “ice house” environment [112, 113]. This transition was accompanied by major shifts in global climatic envelopes and the reorganization of mammalian communities [6, 14, 29, 34, 52]. For mammalian community connectedness there are two possible scenarios. First, while the environment was shifting, lineages may have adapted in place and overall trophic structure and community connectedness would have remained relatively constant through time, as observed during the Neogene of Europe [55]. Alternatively, species may have shifted ranges and changed the average set of taxa present at a locality which would be associated with non-stationary trophic structure and community connectedness.

At a regional scale, North American community connectedness is expected to follow the global predictions described above because the vast amount of prior synthesis has focused on North America [4–6, 9, 10, 14, 29, 36, 37, 99, 100]. However, the effect of global climate change on North American diversity remains unresolved and controversial [6, 10, 14, 29], thus it is necessary to determine empirically when global versus regional versus local scale processes may have been important and how that may have changed over time.

The European mammalian fossil record is also well studied, though research has primarily focused on the Neogene [54, 55, 65, 81–83]. An important aspect about the European record is that during the Neogene there was little shift in relative dietary category abundance [55] and that the patterns within herbivores (browse–graze transition) were mostly driven by abundant, cosmopolitan taxa [54]. It is predicted then that herbivores will demonstrate the same patterns of community connectedness as Europe as a whole, while omnivores and carnivores will be different from that of herbivores and may demonstrate random or constant patterns of community connectedness through time.

Patterns of community connectedness for South American mammalian fauna are comparatively less synthesized than those of North American and Europe. Instead, cross-continental dynamics between North and South America during the Neogene are much more studied [71]. The South American mammalian faunal record reflects two distinct biotic provinces between the North and the South [30, 68, 69, 76]. Because of this, it is expected that South America will have a different pattern of community connectedness than either North America or Europe. Also, there is an expected dramatic increase occupancy in land-dwelling herbivores relative to arboreal and scansorial taxa related to the aridification of high-latitude South America. Additionally, because of this strong biome distinction, it is predicted that provinciality will be high but remain constant over time.

Proposed research: Using an approach proposed by Sidor et al. [95] and Vilhena et al. [109], I will use bipartite biogeographic networks in order to understand patterns of community connectedness. Networks are between taxa, here defined as species, and localities, defined as 2x2 grid cells from an equal-area map projection. Networks will be made for every 2 million year bin of the Cenozoic. This bin width is chosen to always have a minimum of two localities present. Networks will also be constructed for taxa separated by dietary and locomotor category. Previous studies of mammalian occurrence patterns have restricted analysis to

large bodied and well studied groups, such as Primates and Artiodactyls, in order to account for potential sampling and taxonomic biases. Here, analysis will be done using all available taxa and with a restricted sample of just major groups in order to observe any differences in patterns of community connectedness.

Community connectedness will be measured using the four summary statistics described above. E is defined as $E = \frac{\sum_{i=1}^L \frac{u_i}{n_i}}{L}$ where L is as the number of localities, u is the number of taxa unique to a locality, and n is the number of taxa present at a locality. This is a measure of how unique localities are on average. Occ is the number of localities a taxon is, on average, found at and is defined $Occ = \frac{\sum_{i=1}^N \frac{l_i}{N}}{N}$ where N is as the number of taxa present in the biogeographic network and l is the number of localities a taxon occurred in. BC is a measurement of the shared taxa between localities and is defined $BC = \frac{O-N}{LN-N}$ where O is the total number of taxonomic occurrences. BC ranges from 0 to 1, with 0 meaning that each locality completely disconnected from all other localities and 1 indicating that all taxa are presents at all localities.

Code length is a measure of the information flow [94] of a graph as estimated from the behavior of a random surfer [16] on a graph and how often it visits each node and it's behavior with regards to moving into and out of different regions of the graph. Code length is the minimum length of a binary code for describing the behavior the surfer and the community structure of the nodes and is estimated via the map equation [89, 90]. The logic of the map equation is that a good map compresses reality into as few symbols as possible thus we want to compress as many nodes as possible into as few symbols as possible. Our goal is to represent a graph better than just assigning a unique Huffman code to each node [42, 89]. By compressing multiple nodes into a single code block, we decrease the minimum coding length of a network and a network with a low code length has more nodes compressed into distinct subunits/provinces without losing the underlying information flow of the graph. In the case of measuring community connectedness, a low code length means greater site distinctness and provinciality than a graph with a high code length [95].

Phylogenetic similarity between localities may play an important role in community structuring [111] such as closely related taxa being "repulsed" due to competitive exclusion or "clumped" because of environmental filtering. As a preliminary approach, for every pairwise combination of localities during a time period an informal phylogeny will be constructed for the pool of all taxa present in both localities. This informal phylogeny will be based solely on available taxonomic information such as order, family, and genus assignments. The average patristic distance between all taxa will then be estimated. The average of all pairwise comparisons can then be used in partial correlations and modeling questions for understanding what best explain patterns of community connectedness. Other metrics such as those described in Helmus et al. [41] for measuring phylogenetic species variability and phylogenetic species richness, for example, will also be considered as alternative measures of phylogenetic community similarity.

The next step is to compare patterns of community connectedness both within and between regions in order to understand if global, regional, or local scale processes dominate. Addition-

ally, comparisons will be done between the different dietary and locomotor categories both within and between regions to determine which scale processes may be affecting either trait. The approach and methodology to accomplish these analyses is currently under development. Additionally, the possibility of integrating locality–locality distance or some other measure of topology will be explored, especially how this relates to code length and provinciality in general.

The data necessary to complete this study is the same as for the above analysis of mammalian survival.

Preliminary results Preliminary results of the community connectedness patterns of both North America and Europe based on PBDB data are presented here (Fig. 2). Both regions have qualitatively different patterns of community connectedness, primarily during the Paleogene. Almost all four of the summary statistics are extremely volatile over the Cenozoic, especially for Europe. However, some interesting qualitative patterns are present.

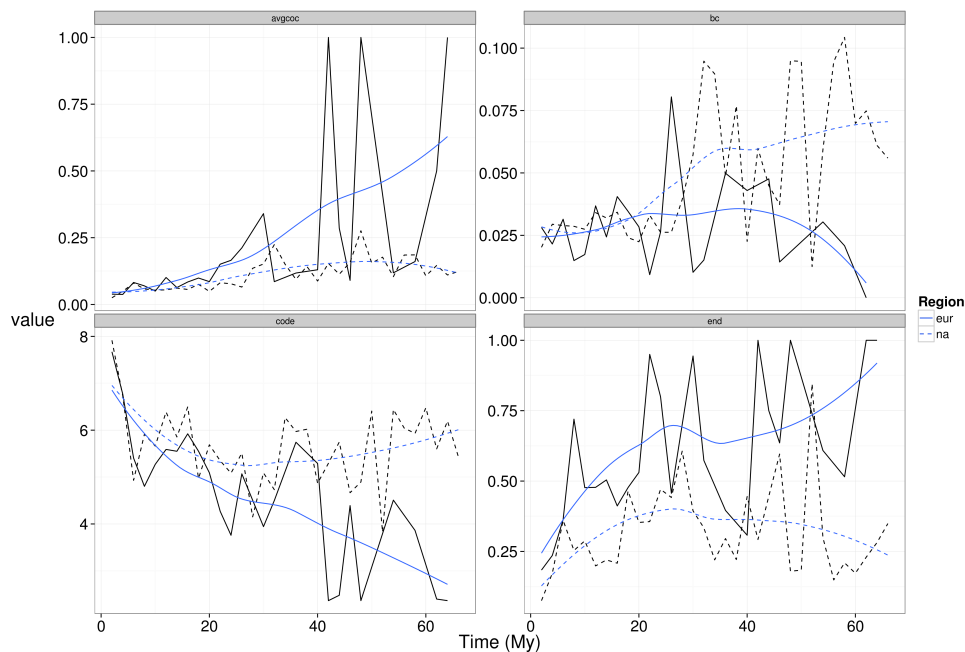

Figure 2: Biogeographic network summary statistics for mammalian communities in North America (dashed line) and Europe (solid line). The summary statistics are, clockwise from top left: average relative occupancy (avgcoc), biogeographic connectedness (bc), average relative number of endemics (end), code length (code). Blue lines are generalized additive model smooths and are presented to illustrate the over all pattern of the two regions.

There is a qualitative decrease in *Occ* in Europe until approximately the start of the Neogene (approximately 23 My), indicating that the average taxon is becoming generally less cosmopolitan over time. In contrast, North American *Occ* is qualitatively stationary over the entire Cenozoic and almost always lower than that observed for Europe. This means that, on

average, North American taxa are present in very few localities at any given point in time.

In Europe there is a qualitative rise in BC in the first few million years of the Cenozoic, but afterwards remains relatively stationary meaning that the average proportion of shared taxa remained qualitatively stationary. In comparison, North American BC remains stationary with a greater amount of shared taxa than Europe for the first half of the Cenozoic followed by a decrease and another plateau at the end of the Cenozoic.

In Europe, there is a over all qualitative decrease in E while in North America there is a qualitatively constant E over the Cenozoic with a slight decrease in the Neogene. As discussed above, E is a measure of relative uniqueness of a locality on average. Qualitatively, North America retained approximately the same amount of site uniqueness through out the Cenozoic. While the pattern of the European record shows a qualitatively nonmonotonic decrease in locality uniqueness.

The code length of European biogeographic networks increases qualitatively over the entire Cenozoic, while code length of North American networks remains relatively constant until the Neogene when there is a qualitative increase. Initial interpretation of these results indicates that North America maintains a relatively stationary degree of provinciality while Europe has a qualitatively decreasing degree of provinciality.

Summary of proposed research

One of the most important questions in (paleo)biology is why do certain taxa go extinct while others do not? Elucidating what traits are important when estimating survival is extremely important and a fundamental concern of evolutionary paleoecology. While the emergent property of range size is continually found to be extremely vital for both origination and extinction [33, 39, 45, 50, 91], how candidate constituent lower level traits interact and “form” range size remains more nebulous and is instead frequently framed as which traits are important in addition to range size [33, 38, 73]. If the best models of survival include the additive or interactive effects of multiple organismal traits then this is possibly the signature of emergence, particularly in the case of interaction. Related to this is the “law” that extinction risk within an adaptive zone is taxon age independent [106]. Here I analyze two biologically different clades in order to understand patterns of survival and expectations of whether global, regional, or local scale process should dominate. By comparing the patterns of survival in brachiopods and mammals it should be possible to determine when different variables matter to survival and when they do not and potentially how they matter.

Timeline

Spring/Summer 2014

- Evolution Meeting: preliminary brachiopod survival results
- South American fossil mammal data from Field Museum of Natural History collections

Fall 2014/Winter 2015

- GSA: survivorship simulation for anagenesis and sampling
- Doctoral Dissertation Improvement Grant

Spring/Summer 2015

- Evolution Meeting: mammalian survivorship analysis for North America and Europe
- South American fossil mammal data from American Museum of Natural History collections
- write and submit survivorship simulation paper

Fall 2015/Winter 2016

- SVP or GSA: mammalian biogeographic connectedness
- write and submit mammal connectedness paper

Spring/Summer 2016

- Evolution Meeting: brachiopod survival analysis results
- write and submit brachiopod survival paper

Fall 2016/Winter 2017

- SVP or GSA: mammalian survivorship analysis
- write and submit mammal survival paper

Spring/Summer 2017

- Evolution Meeting
- write and submit review/philosophy paper
- **Defend**
